Explosive Hyperinflation, Inflation-Tax Laffer Curve, 
and Modeling the Use of Money

by

MARÍA -JOSÉ GUTIÉRREZ AND JESÚS VÁZQUEZ

This paper analyzes the existence of an inflation-tax Laffer curve (ITLC) in the context of two optimizing monetary models. Explosive hyperinflation rules out the presence of an ITLC. In a cash-in-advance economy, this paper shows that explosive hyperinflation is possible and thus an ITLC is ruled out whenever the relative risk aversion parameter is greater than one. In a money-in-the-utility-function model, it is shown that (i) an ITLC is also ruled out and (ii) explosive hyperinflations are more likely when the transactions role of money is more important. (JEL: E 31, E 41)

1 Introduction

Hyperinflation is usually viewed as the result of an inflationary finance policy. The rationale for an inflationary finance policy is that generating inflation through a persistent rise in the money supply can be understood as a means of raising revenues for the government by using an inflation tax.1 Most of the inflationary finance models developed in the literature (for instance, EVANS AND YARROW [1981], KIGUEL [1989], BRUNO [1989], and BRUNO AND FISCHER [1990]) are built on Cagan’s demand for money (CAGAN [1956]). Under perfect foresight those models imply the possibility

---

1 It must be clear that an inflationary finance policy might not result in an optimal inflation tax raised by a benevolent social planner. Then why should a government and monetary authorities adhere to a technical, presumably grossly inefficient, inflationary finance policy? There are, at least, two complementary reasons, which are well documented in the inflationary finance literature. First, most hyperinflationary episodes are driven mainly by huge government spending after some very destructive war. Second, printing money is usually the easiest way to finance huge government expenditure when it is difficult to increase taxes due to lack of political consensus and to weakness of government.
of dual equilibria and the existence of a (concave) inflation-tax Laffer curve (ITLC), which means that inflation does not explode. Based on this traditional approach, a recurrent theme in the large empirical literature on hyperinflation (Cagan [1956], Sargent [1977], Taylor [1991], Phylaktis and Taylor [1993], and Kiguel and Neumeyer [1995], among others) is the analysis of whether the economy is on the efficient side of the ITLC (that is, whether the inflation tax is increasing in inflation during a hyperinflationary episode).²

This traditional approach has recently been challenged because it fails to explain many stylized facts observed during hyperinflation. For instance, Buitrer [1987], Dornbusch, Sturzenegger, and Wolf [1990], Bernholz and Gersbach [1992], and Vázquez [1998] emphasize that hyperinflation is better characterized by an unstable dynamic process where inflation speeds up and real money balances tend to vanish.

This paper uses an analytical approach to examine whether explosive hyperinflation is possible and thus to study whether an ITLC is ruled out. We consider two standard optimizing monetary models: a cash-in-advance model and a money-in-the-utility-function model. The two models represent alternative ways of modeling the role of money as a medium of exchange. In both models the representative agent’s preferences are represented by a constant-relative-risk-aversion utility function. Interestingly, one can show that the money-in-the-utility-function model reduces to the cash-in-advance model when money is strictly essential for purchasing goods. We argue that a cash-in-advance model (or alternatively, a money-in-the-utility-function model with money being essential) is a sensible approach to analyzing hyperinflationary scenarios because extreme inflation dramatically decreases credit transactions and in general the use of long-term contracts. This implies that money becomes more essential for purchasing goods during hyperinflation than during stable periods. There are two main well-known reasons to avoid the use of long-term contracts during hyperinflation: first, the rapid depreciation of money during hyperinflation, which induces agents to spend money as soon as they have got it (Casella and Feinstein [1990] report anecdotal evidence on this issue); second, the instability of relative price movements during hyperinflation (see Tang and Wang [1993] for empirical evidence on this issue), which induces large uncertainty about the outcomes of long-term contracts.

In the context of a cash-in-advance economy, we show that an ITLC arises if and only if the relative risk aversion parameter is less than one. This means that an ITLC is possible whenever the relative risk aversion parameter lies outside the usual range assumed, which implies an unrealistically high intertemporal substitution for consumption.³ Moreover, explosive hyperinflation can arise in this framework only if the relative risk aversion parameter is greater than one. In the context of an

² The term ITLC refers to a concave (hump-shaped) function relating inflation tax to inflation. Alternatively, we can also define the ITLC as a hump-shaped function that relates inflation tax to real money balances.

³ Auerbach and Kotlikoff [1987] consider that reasonable values for the relative risk aversion parameter lie in the range 2 to 10.
optimizing model with money in the utility function, this paper shows that explosive hyperinflation is more likely when the transactions role of money becomes more important. Moreover, we show that an ITLC is also ruled out in a money-in-the-utility framework unless other restrictions are imposed, for instance, that the utility function is additively separable in consumption and real money balances and that the utility function assumed for real money balances satisfies certain restrictions.

The main contribution of this paper is to provide a characterization of agents’ preferences that are compatible with an ITLC and thus with stable hyperinflation or, alternatively, with explosive hyperinflation. Our characterization shows that stable hyperinflation is possible only if agents’ preferences are described by an unrealistic relative risk aversion parameter. However, explosive hyperinflation is possible if the relative risk aversion parameter lies inside the usual range, that is, if preferences have curvature greater than the logarithmic utility function. This characterization may help to assess the welfare costs associated with a stabilization policy carried out during hyperinflation, since the type of preferences assumed must be consistent with the way the researcher views hyperinflation (as a stable process or, alternatively, as an explosive dynamic process).

The optimizing monetary models considered in this paper are characterized by a unique unstable steady state. A skeptical reader may argue that any model of hyperinflation must be also able to explain the case of stable low inflation. Like Obstfeld and Rogoff [1983], we do not share this view, since a model of hyperinflation can be extremely stylized – assuming, for instance, that to a great extent the classical dichotomy between real and nominal variables holds in a hyperinflationary scenario. Moreover, money demand is usually assumed to depend only on expected inflation in analyzing hyperinflationary episodes, and then it does not depend on real income as it does in low-inflation periods. From our point of view, it is clear that in order to characterize low-inflation dynamics one needs to specify a more complex money demand than the one assumed in hyperinflationary models. But for the same reason, it is hard to believe that a simple function characterizing money demand during hyperinflationary periods would be appropriate to characterize the dynamics of low and stable inflation.

More generally, hyperinflation distorts economies in many ways. Some examples are the following. First, money becomes essential for agents engaging in transactions. Thus, as pointed out by Casella and Feinstein [1990], economic exchange patterns during hyperinflation are dramatically different from those observed in low-inflation periods. Second, nominal anchors such as price and wage indexation tend to disappear during hyperinflation, affecting inflationary dynamics. Third, expectational dynamics can change substantially in the transition from a low-inflation scenario to a high-inflation one. Thus, adaptive learning can be appropriate to modeling expectations when inflation is low. However, when inflation reaches high

Obstfeld and Rogoff [1983] characterize explosive hyperinflation in the context of a money-in-the-utility-function model where the utility function is additively separable in consumption and real money balances. In their model, there is a unique unstable steady state, as in the models studied in this paper.
levels, agents most likely respond rapidly to changes in inflation, and instantaneously during hyperinflation, since systematic mistakes in forecasting inflation result in prohibitive costs. The analysis of expectational dynamics has already been pursued in a recent paper by MARCET AND NICOLINI [2003] aiming to explain recurrent hyperinflations.

We believe that introducing some of these features in a model would be useful for characterizing the dynamics of the transition from a low-inflation steady state to a high-inflation one. However, the aim of this paper is different and rather modest. We try to characterize explosive hyperinflation where an economy is just in a high-inflation scenario, there is perfect foresight, money demand depends only on inflation, and money is essential. The point raised in this paper is that hyperinflationary dynamics derived from standard maximizing models are consistent with a characterization of hyperinflation as an explosive process. However, these models are not consistent with a characterization of the economy being on the inefficient side of the inflation-tax Laffer curve as suggested in traditional inflationary finance models.

The rest of the paper is organized as follows. Section 2 characterizes the existence of an ITLC (which implies the existence of an inflation-tax maximization rule) in terms of a money-demand restriction. Moreover, that section reviews the approach followed in the empirical literature in order to analyze whether the economy is on the efficient side of the ITLC where the ITLC is increasing (decreasing) in inflation (real money balances). Section 3 studies a cash-in-advance economy. Section 4 studies an optimizing model with money in the utility function. Section 5 concludes.

2 Inflation-Tax Laffer Curve

Inflationary finance models usually assume that a constant per capita share of government’s deficit \( d \) is financed by issuing high-powered money. Formally,

\[
\frac{\dot{M}(t)}{P(t)} = d,
\]

where \( M(t) \) is the per capita nominal money supply at time \( t \) and \( P(t) \) is the price level. As usual, a dot on a variable denotes its time derivative.

Using the latter expression, denoting per capita real money balances by \( m(t) \) and omitting the time index for the sake of simplicity, we can write the law of motion for real money balances as follows:

\[
\dot{m} = d - m \pi,
\]

where \( \pi \) is the rate of inflation (that is, \( \dot{P}/P \)). The inflation tax \( T^i \) is defined as the loss of purchasing power of a unit amount of nominal money balances due to the existence of a positive inflation rate. Formally,

\[
T^i = m \pi.
\]
According to (1), real money balances decrease whenever the inflation tax is greater than \( d \) (that is, the share of government’s deficit that is financed by issuing high-powered money). Since \( d \) is a constant, we can conclude from (1) and (2) that \( T' \) is strongly concave (convex) if and only if \( m \) is a strongly convex (concave) function of real money balances.

The traditional approach builds upon Cagan’s demand for money,

\[
\ln(m) = \kappa - \mu \pi, \tag{3}
\]

where \( \kappa \) is a positive constant and \( \mu \) is the (positive and constant) semielasticity of money demand with respect to the nominal interest rate. Based on (3), Figures 1 and 2 summarize the two well-known key aspects of the traditional view of hyperinflationary dynamics. First, two steady states may coexist for a given level of government deficit \( d \) whenever this level is not too high and \( \kappa \) and \( \mu \) are determined accordingly. Second, a high-inflation trap exists in that the high-inflation steady state, \( m_1 \), is stable and the low-inflation steady state, \( m_2 \), is unstable. Notice that the high-inflation steady state is on the wrong side of the ITLC, that is, an increase in real money balances raises the inflation tax (or alternatively, a decrease in inflation raises the inflation tax).

A hump-shaped ITLC is characterized by the existence of a level of real money balances for which the ITLC is maximized. Let us assume that the demand for money is a general decreasing function of the inflation rate, the inverse of the money demand function exists, and the money market clears instantaneously. The inverse of the money demand function, \( f \), is given by \( \pi = f(m) \) with \( f'(\cdot) < 0 \). The following proposition relates the inflation-tax maximization rule to the demand for money.

\[\text{Figure 1} \quad \text{Law of Motion for Real Money Balances}\]
**PROPOSITION 1** Assume that an ITLC exists (that is, $T_i$ is strongly concave). The inflation tax is maximized when the amount of real money balances is such that the elasticity of the inverse of the demand-for-money function, $\eta_f$, is one.

**PROOF** The inflation tax is given by $mf(m)$. The first-order condition for inflation-tax maximization is

$$m^* f'(m^*) + f(m^*) = 0,$$

where $m^*$ denotes the level of real money balances that maximizes the inflation tax. Denoting the elasticity of the inverse of the money demand function with respect to real money balances by $\eta_f$, that first-order condition can be written as follows:

$$\eta_f = -f'(m^*) \frac{m^*}{f(m^*)} = 1.$$  (4)

The second-order condition given by

$$2f'(m^*) + m^* f''(m^*) < 0$$

establishes the condition for a maximum (that is, the condition characterizing a strongly concave ITLC). The proof is completed. Q.E.D.

Notice that equation (4), in general, characterizes the inflation-tax maximization rule because, as we shall show below, an inverse money demand function, such as $f(.)$, typically arises from an agent’s optimization problem. Even if $f(.)$ includes more arguments than $m$ (for instance, the real interest rate and the level of income), the condition (4) still characterizes the inflation-tax maximization policy if $f'(.)$ is replaced by $f_m(.)$ (i.e., the partial derivative of $f$ with respect to $m$).

The empirical literature on hyperinflation analyzes whether huge inflation rates are consistent with the policy of maximizing the inflation tax on the part of monetary authorities. Notice that an inflation-tax maximization rule only makes sense when the inflation tax function $T_i$ has a maximum. By using Proposition 1 (equation (4)), we can easily show the well-known result that when the demand for money is
characterized by Cagan’s expression (3), the rate of inflation that maximizes the inflation tax is given by the reciprocal of the semielasticity of demand for money with respect to the nominal interest rate, $1/\mu$. Thus, the empirical literature on hyperinflation built on Cagan’s demand for money usually tests whether inflation dynamics are consistent with an inflation-tax maximization rule by first averaging the rate of inflation over the sample period, and then testing whether or not the average inflation is significantly different from $1/\hat{\mu}$, where $\hat{\mu}$ is the estimated value of $\mu$.

We think that this way of proceeding is subject to two caveats. First, it relies on an ad hoc form of characterizing money demand. Second, since the inflation process seems to be nonstationary during hyperinflation, averaging the rate of inflation over the sample period might not be appropriate. The first caveat (arguably) is a mild one because, on the one hand, Cagan’s money demand fits the data reasonably well in most hyperinflationary episodes studied in the literature; and on the other hand, as shown by Calvo and Leiderman [1992], Cagan’s expression can be derived from first principles by assuming that money enters directly into the utility function and by considering a particular functional form of the utility function for money. The second caveat is more serious, because inflation is always rising during hyperinflationary periods. The rise in inflation could be due, firstly, to the fact that inflation really follows an explosive (nonstationary) process or, alternatively, to the fact that the inflation rate follows the convergence path leading to a steady-state rate of inflation. In either case, the consideration of the average rates of inflation over the sample period is, at least, problematic because, in the former case, the average is specific to the sample period (that is, the first moment of the inflation process does not exist), and in the latter case, averaging the rates of inflation over the sample period does not approximate well the steady state of the inflation rate.

Due to these limitations of the empirical evidence found following the traditional approach, we henceforth follow an analytical strategy by studying, in the context of two optimizing monetary models, whether the huge rates of inflation observed during hyperinflationary episodes are consistent with an ITLC – which implies a stable dynamic process for real money balances and inflation as described by the high-inflation steady state represented in Figures 1 and 2 – or, alternatively, those huge rates of inflation are the result of an unstable dynamic process that leads to explosive hyperinflation.

3 A Cash-in-Advance Economy

The two optimizing monetary models considered in this paper assume a continuous-time model where the economy consists of a large number of identical infinite-lived households. There is no uncertainty. Each household has a nonproduced endowment $y(t) > 0$ of the nonstorable consumption good per unit of time. In the cash-in-advance model, the representative household’s utility at time $0$ is
where $c(t)$ is per capita consumption, $U(.)$ is the increasing and concave utility function, and $0 < r < 1$ is the constant subjective discount rate, which, following Calvo [1987], is assumed to be equal to the real rate of interest. As shown below, this assumption implies that the demand-for-money function is time-invariant, like the one assumed in the traditional inflationary finance literature. The utility function is further assumed to be of the constant-relative-risk-aversion class, given by
\[
U[c(t)] = \frac{[c(t)]^{1-\alpha} - 1}{1 - \alpha},
\]
where $0 < \alpha < \infty$ denotes the constant relative risk aversion parameter that measures the curvature of the utility function. We define the financial wealth and the nominal interest rate as
\[
w(t) = m(t) + b(t),
\]
\[
i(t) = r + \pi(t),
\]
respectively, where $b(t)$ denotes real per capita government debt. The household’s budget constraint is
\[
\dot{w} = rw(t) + y(t) - \tau(t) - [c(t) + i(t)m(t)],
\]
where $\tau$ is a lump-sum tax (government transfer if negative), and the term in brackets is the full consumption, that is, the sum of consumption and costs of holding money.

In addition, as in the cash-in-advance literature, we assume that money is strictly essential to buy the consumption good. In particular, in order to consume $c$ units of the consumption good at time $t$, the household must hold a stock of real money balances, $m$, greater than or equal to $c$. Formally,
\[
m(t) \geq c(t).
\]
At time 0 the household chooses the paths of $c$ and $m$ in order to maximize (5) subject to (7) and (8). Assuming the existence of an interior solution for $c$, and that money is return-dominated by the government bonds (that is, $i(t) = r + \pi(t) > 0$, and this implies that (8) holds with equality), the following first-order condition is obtained from the household’s optimization problem:
\[
[m(t)]^{-\alpha} = \lambda[1 + i(t)],
\]
where $\lambda$ is the associated Lagrange multiplier, which is time-invariant because the instantaneous rate of discount is assumed to be equal to the real rate of interest.

Moreover, empirical papers on hyperinflation aim to uncover a stable (time-invariant) demand for real money balances in such unstable scenarios. By working with a time-invariant demand for real money balances, we aim to convince the reader that our results are not driven by an unstable demand for real money balances.

We focus our attention on this class of utility functions because they play a central role in modern intertemporal macroeconomics.
Then equation (9) characterizes the time-invariant demand for real money balances. The transversality condition implies that
\[
\lim_{t \to \infty} e^{-rt} \lambda w(t) = 0.
\]
By using the definition of the nominal interest rate, and after a little algebra, equation (9) can be written as follows:
\[
\pi(t) = \left[ m(t)^{-\alpha} - k \right] \lambda,
\]
where \( k = \lambda (1 + r) \) is a constant. Notice that equation (11) is truly the inverse of a demand-for-money function, thus relating the rate of inflation to real money balances. The following proposition characterizes the rate of inflation and real money balances that are consistent with the inflation-tax maximization rule, and thus with an ITLC, as a function of the relative risk aversion parameter \( \alpha \) and the rate of discount, \( r \).

**Proposition 2.** Assume a cash-in-advance economy and that the utility function is characterized by a constant relative risk aversion parameter \( \alpha \). There is a (strongly concave) ITLC if and only if \( \alpha < 1 \). Moreover, the rate of inflation that maximizes the inflation tax is given by
\[
\pi^* = \left( \frac{1 + r}{1 - \alpha} \right)\lambda
\]

**Proof.** The first part of the proposition is proven by showing that \( T^i \) is a strongly concave function if and only if \( \alpha < 1 \). After some calculation, we can show that
\[
\frac{\partial^2 T^i}{\partial m^2} = \frac{\alpha(\alpha - 1)}{\lambda(m(t))^{1+\alpha}},
\]
which implies that there is an ITLC (that is, \( \partial^2 T^i / \partial m^2 < 0 \)) if and only if \( \alpha < 1 \).

By using equation (11), the inflation tax maximization condition (4) can be written as follows:
\[
1 = \eta_f = \alpha(m^*)^{-\alpha} \frac{m^*}{(m^*)^{-\alpha} - k},
\]
which implies
\[
(m^*)^{-\alpha} = \frac{k}{1 - \alpha}.
\]
Substituting equation (13) in equation (11), we have that
\[
\pi^* = \left( \frac{1 + r}{1 - \alpha} \right)\lambda.
\]
Thus, the proof is completed. **Q.E.D.**

Proposition 2 establishes that huge inflation rates under the inflation-tax maximization rule occur when \( \alpha \) is smaller than (but close to) one. Furthermore, when \( \alpha \) is equal to one (that is, the utility function is logarithmic), there is no (finite) inflation rate maximizing the inflation tax.
As shown in section 1, a strongly convex \( \dot{m} \) (or alternatively, a strongly concave \( T' \)) is consistent with the traditional view of describing hyperinflation as a stable dynamic process. Therefore, Proposition 2 shows that in the context of a cash-in-advance economy the condition \( \alpha < 1 \) is necessary and sufficient to characterize hyperinflation as a stable dynamic process.

We now turn to describing hyperinflation as an unstable dynamic process. In particular, the following proposition shows that if \( \alpha > 1 \), hyperinflation can be characterized as an explosive dynamic process.

**Proposition 3** Assume a cash-in-advance economy and that the utility function is characterized by a constant relative risk aversion parameter \( \alpha \). The law of motion of real money balances is a strongly concave function (i.e., \( \partial^2 \dot{m} / \partial m^2 < 0 \)), and \( \lim_{m \to 0} \dot{m} = -\infty \) if and only if \( \alpha > 1 \).

**Proof** The first part of Proposition 3 is a direct corollary of Proposition 2, since \( T' \) is strongly concave (convex) if and only if \( \dot{m} \) is strongly convex (concave). The second part is proven by taking into account (1) and then showing that

\[
\lim_{m \to 0} \dot{m} = \lim_{m \to 0} \left( d - \frac{1}{\lambda m^{\alpha-1}} \right) = \begin{cases} 
-\infty & \text{if } \alpha > 1, \\
\frac{d - \lambda^{-1}}{\lambda} & \text{if } \alpha = 1, \\
\frac{d}{\lambda} & \text{otherwise}.
\end{cases}
\]

Thus, the proof is completed. \( Q.E.D. \)

Figure 3 describes hyperinflation as an unstable dynamic process. Notice that to the left of the steady state \( m^* \), the economy will be moving along an unstable hyperinflationary path where real money balances tend to vanish and inflation explodes. Along these hyperinflationary paths the transversality condition (10) always holds,
since real money balances tend to vanish and financial wealth \( w(t) \) tends to be determined entirely by \( b(t) \), and it is reasonable to assume that \( b(t) \) has an upper bound. Moreover, notice that the hyperinflationary paths generated by a cash-in-advance economy do not cross the vertical axis. The rationale is that a cash-in-advance constraint means that money is essential for purchasing and consuming goods. Therefore, the marginal utility of consumption goes to infinity as real money balances go to zero, since the Inada condition \( U'(0) = \infty \) is satisfied by (6). The fact that the marginal utility of consumption goes to infinity implies that the inflation tax \( T' \) goes to infinity (and \( \dot{m} \) goes to minus infinity) whenever \( \alpha > 1 \), since inflation (which is an increasing function of the marginal utility of consumption) in this case grows more rapidly than real money balances decrease when the latter go to zero.

In sum, we have shown in this section that the huge rates of inflation observed during hyperinflation are consistent with explosive inflation in a cash-in-advance economy if and only if the relative risk aversion parameter is greater than one. However, an ITLC in a cash-in-advance economy is not consistent with huge inflation rates unless an unrealistically high intertemporal substitution for consumption (that is, \( \alpha < 1 \)) is assumed.

Next section shows that money-in-the-utility-function models do not generate feasible hyperinflationary paths, nor does an ITLC arise, unless some particular restrictions are imposed.

### 4 Money-in-the-Utility Function

The model considered in this section only differs from the model studied in the previous section in three aspects. First, we assume that the representative household’s utility at time 0 is

\[
\int_0^\infty e^{-\rho t} U[c(t), m(t)] dt.
\]

Following Bental AND Eckstein [1997], we assume a constant-relative-risk-aversion utility function. In particular, we assume that

\[
U[c(t), m(t)] = \frac{\left[c(t)^{1-\omega} m(t)^\omega\right]^{1-\alpha} - 1}{1 - \alpha},
\]

where \( \omega \) is a parameter measuring the transaction requirement of money. A value of \( \omega \) close to zero implies that money is not essential in buying consumption. The higher \( \omega \) is, the more important the transactions role of money becomes. Second, it is assumed that there is a lower bound on real money balances, \( \hat{m} \geq 0 \). Formally,

\[
m(t) \geq \hat{m}
\]

for all \( t \). As discussed below, the restriction (16) guarantees the existence of hyperinflationary paths. Finally, there is no cash-in-advance constraint such as (8).

This is an optimization problem with a bounded control. The solution to this problem is obtained (see Kamien AND Schwartz [1991]) by using the Lagrangian
that is obtained by appending the constraint (16) to the corresponding Hamiltonian. Let us denote by $\hat{t}$ the period when the real money balances reach $\hat{m}$. The first-order conditions obtained from the household’s optimization problem (that is, maximize (14) subject to (7) and (16)) imply that for any $t < \hat{t}$ the marginal rate of substitution between real money balances and consumption is equal to the nominal interest rate. Assuming that $U[c(t), m(t)]$ is given by (15), this condition can be written as follows:

$$\frac{\omega c(t)}{(1 - \omega)m(t)} = \pi(t),$$

or alternatively,

$$\pi(t) = \frac{\omega c(t)}{(1 - \omega)m(t)} - r. \tag{17}$$

Notice that, as in the cash-in-advance model, we also assume that the discount rate is equal to the real rate of interest. Taking into account (17), the law of motion for real money balances is

$$\dot{m} = d - \frac{\omega c(t)}{1 - \omega} + r m(t).$$

This expression shows that the law of motion for real money balances is a linear and increasing function of $m$. Moreover, there is a steady state only when $d \leq (\omega c(t))/(1 - \omega)$ for all $t$. This unique steady state is unstable. Notice that the closer $\omega$ is to one (that is, the more important the transactions role of money is), the more likely the existence of an unstable hyperinflationary path is. Figure 4 displays the dynamics of real money balances in this framework. Notice that to the left of the steady state $m^*$, the economy will be moving along an unstable hyperinflationary path where real money balances go to $\hat{m}$ and inflation speeds up. Imposing a lower bound on real money balances, $\hat{m}$, prevents the $\dot{m}$ schedule from eventually
crossing the vertical axis at some finite point, which would imply negative real balances. This type of restriction is relevant because some authors (for instance, Obstfeld and Rogoff [1983]) have argued that paths implying negative real money balances are impossible in a perfect-foresight framework and therefore must be excluded from the class of possible paths. However, one must notice that (16) is an ad hoc restriction and that the existence of a lower bound on real money balances is not easy to motivate in the context of a money-in-the-utility-function model.7

From the previous analysis one can draw the conclusion that possible hyperinflationary paths (those hyperinflationary paths satisfying first-order conditions and implying always nonnegative real money balances) arise naturally in the basic cash-in-advance model studied in section 3. However, money-in-the-utility-function models place certain limitations on generating hyperinflationary paths. In particular, these limitations appear in the money-in-the-utility-function model when real money balances and consumption are substitutes. As shown by Obstfeld and Rogoff [1983], if the utility function is additively separable in consumption and real money balances, hyperinflationary paths cannot be ruled out unless other, severe restrictions are imposed on individual preferences. This discussion points to the conclusion that the basic cash-in-advance model is a natural framework to analyze explosive hyperinflation in that there is no need to impose additional restrictions in this framework to generate hyperinflationary paths.

It is interesting to notice that the money-in-the-utility-function model reduces to the cash-in-advance model in the extreme case that $\omega = 1$ (that is, money is strictly essential), since equation (15) then becomes (6) with the cash-in-advance constraint (8) already substituted into the utility function (6). Therefore, the cash-in-advance model can be viewed as the limiting case of a money-in-the-utility-function model when money is considered strictly essential (that is, when $\omega = 1$). As argued in the Introduction, a cash-in-advance model (or, alternatively, a money-in-the-utility-function model assuming that money is strictly essential) is a sensible approach to study hyperinflation, since huge inflation rates cause credit transactions to vanish and money to become strictly essential for purchasing goods.

Finally, we consider the case where the utility function is additively separable in consumption and real money balances:

\begin{equation}
U[c(t), m(t)] = U[c(t)] + V[m(t)],
\end{equation}

where $U(.)$ and $V(.)$ are increasing and concave functions. Both utility functions are further assumed to be of the constant-relative-risk-aversion class. In this context, the first-order condition obtained from the household’s optimization problem (that

---

7 In the context of an optimizing monetary model with transaction costs, Vázquez [1998] introduces a lower bound on consumption that, in the transaction-cost monetary model considered in his paper, also implies a lower bound on real money balances. Vázquez [1998] interprets the lower bound on consumption as the threshold at which agents repudiate domestic money and decide to start engaging in barter trading, complete currency substitution, or home production for their own consumption.
is, maximize (14) with $U(c(t), m(t))$ given by (18) subject to (7)) establishes that the marginal utility of real money balances is proportional to the nominal interest rate. Thus, the inverse of the money demand function is given by

$$\pi(t) = f(m(t)) = \frac{V'[m(t)]}{\lambda} - r. \tag{19}$$

After doing the same type of calculation carried out in the proof of Proposition 2, we can show that there is an ITLC whenever the risk aversion parameter characterizing $V'[m(t)]$ is smaller than one. Alternatively, if we specialize

$$V[m(t)] = m(t)[\kappa + 1 - \ln(m(t))],$$

as in Calvo and Leiderman [1992], we have that equation (19) becomes the Cagan money demand (3) and the associated ITLC is the one characterized in section 1.

5 Summary and Conclusions

Two competing approaches have been followed to characterize hyperinflationary dynamics in the literature. The traditional approach posits the presence of an ITLC where the huge rates of inflation observed during hyperinflationary episodes are viewed as the result of the economy being in a stable, but “inefficient,” high-inflation steady state. By contrast, another group of researchers view hyperinflationary dynamics as the result of an unstable dynamic process where real money balances vanish and inflation explodes.

This paper studies two prominent optimizing monetary models to characterize hyperinflationary dynamics. In the context of a cash-in-advance economy, we show that an ITLC is ruled out and explosive hyperinflation is possible whenever the relative risk aversion parameter is greater than one.

In an optimizing model with money-in-the-utility function, an ITLC is also ruled out. Moreover, we show that explosive hyperinflationary dynamics are more likely in this type of model when the transactions role of money becomes important. However, hyperinflationary paths are not possible in this model unless additional restrictions are imposed. Therefore, the money-in-the-utility-function model presents more limitations than the simple cash-in-advance model for characterizing hyperinflation as an explosive process.

Another important conclusion of this paper is that hyperinflationary dynamics derived from standard optimizing monetary models are consistent with a characterization of hyperinflation as an explosive process. However, they are not consistent with a characterization of the economy being on the “inefficient” side of the ITLC (where inflation may be huge, but stable) unless some restrictive assumptions are imposed on agents’ preferences.

It seems that the empirical literature on hyperinflation has been focused on the traditional approach because the econometrics of explosive roots has not been fully developed yet. We believe that pioneer papers on explosive roots (for instance,
JUSELIUS AND MLADENOVIC [1999]) together with theoretical papers on the alternative view of hyperinflation suggest promising avenues for future research on hyperinflationary dynamics.
